ABSTRACT

Water dispersed surface-functionalized superparamagnetic iron oxide nanoparticles (SPIONs) have many applications in various fields and especially in biomedical research. The monodispersity and stability of these nanoparticles and the ability to functionalize their surfaces are critical factors for successful applications. Numerous approaches have been developed that aim at stable and monodispersed SPIONs in aqueous solution. Nevertheless, obtaining water-soluble SPIONs that are stable for prolonged periods (i.e. months) remains challenging. Here, a series of ligands was synthesized featuring nitrocatechol as SPIONs anchor and different polar groups for water solubility. We found that nanoparticles coated with zwitterionic ligands were stable for well over two months, which exceeded the stability of analogues containing negatively charged, positively charged or neutral ligands. A choline phosphate-based zwitterionic ligand was further functionalized with an aldehyde group that facilitated facile additional surface functionalization by means of hydrazone chemistry. These results establish SPIONs as a new platform for reversible covalent surface functionalization, opening up new opportunities in systems chemistry and biomedical applications.

Keywords: dynamic covalent chemistry, surface-functionalization; magnetic nanoparticles; hydrazones.

Introduction

Surface-functionalized superparamagnetic nanoparticles have many applications in various fields, especially in biomedical research, including magnetic resonance imaging (MRI) [1 - 4], hyperthermia treatment of tumors [5 - 6], and magnetic separation of biomolecules and directional drug delivery [7 - 8]. Many of these applications place stringent demands on stability and monodispersity of the SPIONs under physiological conditions [9]. Although the preparation of monodisperse SPIONs in organic media is well-established [10 - 12], making SPIONs that exhibit long-term stability in aqueous solution remains challenging. The common strategies for preparing stable SPIONs in aqueous medium make use of ligands that prevent SPIONs from forming aggregates through electrostatic repulsion or steric effects [13 - 17]. For example, Reimhult and Textor have developed nitrocatechol grafted polymers as stabilizing ligand for SPIONs in aqueous solution [15, 18 - 20]. Also small-molecule spacers carrying charges are commonly applied, as SPIONs coated

with relatively small ligands have a large core/shell ratio which is crucial for magnetic interactions [13]. While several procedures for preparing water soluble SPIONS have been reported, a systematic study comparing the stability of SPIONs coated with different types of polar ligands has not yet

Scheme 1. Structures and synthesis of the zwitterionic, neutral, anionic, and cationic ligands.
been performed. Here, we designed a set of ligands functionalized with the moiety that is most commonly used as the anchor to the SPIONs surface: a nitrocatechol group. The ligands were further equipped with different groups that were expected to endow them with water solubility, including zwitterionic, neutral, as well as anionic, and cationic ones. The stabilities of SPIONs grafted with these ligands were studied in aqueous solution at different pH values and salt concentrations by dynamic light scattering (DLS). We found that aqueous solutions of sulfobetaine-conjugated zwitterionic ligand-coated SPIONs were remarkably stable, showing no signs of aggregation over a period exceeding two months. Another zwitterionic ligand containing a choline phosphate moiety was then synthesized and equipped with an aldehyde group to enable facile further surface functionalization through reversible covalent hydrazone chemistry. These nanoparticles provide a useful platform for future applications in systems chemistry.

Results and Discussion

Ligand Design and Synthesis

The ligands were designed to contain nitrocatechol for anchoring to the SPION surface and a polar group for water solubility. The choice for the catechol anchor was based on the fact that 3,4-dihydroxyphenylalanine and dopamine (Scheme 1) possess a catechol group that has a strong binding affinity for several metal ions [15, 19, 21–23]. These catechol ligands play an essential role in the mussel adhesion mechanism [24]. Inspired by these observations, the catechol moiety has become a popular anchor for the functionalization of iron oxide and titanium oxide nanoparticles [15, 25–26]. However, catechols are readily oxidized by iron(III) to quinones which results in a loss of affinity for the SPION surface, leading to the aggregation of the SPIONs. Introducing a nitro group on the ortho-position of the catechol ring largely prevents catechol oxidation [15, 19].
Water solubility may be achieved with anionic, cationic, zwitterionic, or neutral ligands. We designed and synthesized ligands to represent each of these four classes (Scheme 1). Specifically, we designed the zwitterionic ligand 6 to contain a quaternary ammonium–sulfonate conjugate; the neutral ligand 8 features a biocompatible oligosaccharide [27]. We reasoned that the neutral but large oligosaccharide ligand could potentially stabilize the SPIONs by preventing the exchange of surface ligands with molecules from the environment due to steric hindrance. Similar stabilizing effects of oligosaccharides are often encountered in biological systems, e.g., protein glycosylation can prevent proteases from accessing the peptide backbone, providing resistance to enzymatic degradation [28 - 29]. The anionic ligand 9 contains a carboxylic acid (deprotonated at neutral pH), while cationic ligand 11 features an amine group (protonated at neutral pH).

The synthesis of these four ligands is depicted in Scheme 1. First dopamine was nitrated with NaNO2 in the presence of 20% H2SO4 and then reacted with succinic anhydride to provide compound 2 as an intermediate for further functionalization. The zwitterionic ligand was synthesized by a ring-opening reaction between tertiary amine 3 and propane-1,3-sultone. Deprotection of the resulting compound 4 afforded 5, which was reacted with 2 to yield the desired ligand 6. Oligomaltose was used as a neutral solubilizing group. β-D-maltoheptaosyl azide was reacted with compound 7 through a Cu-catalyzed click reaction to obtain ligand 8. Anionic ligand 9 was synthesized by nitration of 3,4-dihydroxyhydrocinnamic acid. Finally, amidation...
of monoprotected amine 10 with carboxylic acid 2 and deprotection afforded cationic ligand 11. Detailed synthetic procedures and characterization of the four ligands are provided in the Supporting Information.

The preparation of aqueously dispersed SPIONs is depicted in Figure 1. First, oleic acid-stabilized hydrophobic SPIONs were made by the thermal decomposition of iron oleate which was synthesized by an exchange reaction of FeCl3 with sodium oleate [11]. Homogeneous ligand exchange was then applied to obtain water-dispersed SPIONs. Here, a two-step exchange procedure was adopted, because we did not succeed in finding a solvent in which both the oleic acid stabilized SPIONs, and the charged ligands could be dissolved [13]. An intermediate ligand 2-[2-(2-methoxyethoxy)ethoxy]acetate (MEAA) was utilized to exchange the oleic acid attached to the surface of SPIONs. The resulting MEAA-grafted intermediate SPIONs were soluble in a mixture of DMF and water which was a suitable medium for the subsequent exchange with the watersolubilizing ligands. The thus obtained water-dispersed SPIONs were purified by dialysis. The cationic SPIONs aggregated during purification, whereas the other three SPIONs could be dialyzed at least 6 times without any aggregation. All ligand-exchange reactions were conducted in a sonication bath, as magnetic stirring of the nanoparticle dispersions was found to lead to their aggregation.

Characterization of SPIONs

As NMR is difficult for paramagnetic materials the ligand-exchange process was monitored by IR spectroscopy. The IR spectra are shown in Figure S1. C-C single bond and C-H vibrations at ca. 1470 and 2870 cm⁻¹ were observed for oleic acid@SPIONs. After ligand exchange with MEAA, strong absorptions appeared around 1100 and 1200 cm⁻¹ which were assigned to C-O single-bond stretching, while the absorption at 2870 cm⁻¹ became smaller, in agreement with oleic acid having been substituted by MEAA. For the SPIONs functionalized with the water-solubilizing ligands, absorptions due to C=O and C=C stretching at 1450 to 1650 cm⁻¹ were found, together with a C-O single-bond vibration at 1050 cm⁻¹, suggesting that nitrocatechol is present on the surface of the SPIONs. However, it was not possible to quantify the degree of the ligand exchange from the IR spectra. The Fe-O bond around 600 cm⁻¹ is excluded in all spectra, since it is extremely strong compared to the other bands and would compromise the resolution of the remaining part of the IR spectrum.

The morphologies and size distributions of SPIONs were characterized by TEM and DLS. The fresh oleic acid@SPIONs are well-dispersed in hexane which is confirmed by the TEM image in Figure S2. The water-soluble zwitterionic, neutral, and anionic SPIONs are observed as well-dispersed spherical nanoparticles with diameters around 4 – 7 nm in TEM (Figure 2). The hydrodynamic diameters measured by DLS are somewhat larger (Figure S4). However, since the inorganic nanoparticle cores are surrounded by a layer of organic material, and (for the ionic ligands) ions and associated water molecules, which give poor contrast in TEM, these results are in good agreement. Cationic SPIONs precipitated during dialysis, leading to large aggregates found both in TEM (Figure 2) and DLS (Figure S4). The polydispersities measured by DLS for the prepared SPIONs are between 0.2 and 0.3, indicating some degree of aggregation, which is probably inherited from the intermediate MEAA@SPIONs, as MEAA is not a good ligand for stabilizing SPIONs. The SPIONs were not further purified because the number of aggregates was rather low.

The extent of surface coverage of the SPIONs was estimated by thermogravimetric analysis (TGA) [15, 30, 31]. Figure S3 shows that, as the temperature is increased from 20 to 600 °C, several stages of weight loss occur. We interpret the slowly changing weight at 20 to 200 °C to be caused by evaporation of water. The coated ligands start to be decomposed in the range between 200 and 450 °C. The corresponding weight decrease in this range amounts to 19, 27, 25, and 24% for zwitterionic, neutral, anionic, and cationic SPIONs, respectively.
The grafting densities of the ligands were subsequently calculated using Equation S1. The coating density together with the average nanoparticle size, polydispersity, and zeta potential are collected in Table 1. The number of ligands per unit surface area correlates roughly with ligand size: this number is smallest for the large neutral ligand and largest for the anionic ligand, which is the smallest of all.

### Stability Studies

The stabilities of the SPIONs coated with different charged ligands were studied by DLS in aqueous solution at different pH and in the presence of different salts during a period of 70 days. Figure 3 shows the results after two hours.

As shown in Figure 3, A, all of four SPIONs aggregated upon acidification to pH 1, as indicated by the large increase in hydrodynamic size. The zwitterionic SPIONs exhibited the lowest degree of aggregation (mean size of ca. 150 nm, while assemblies of around 1 μm were formed by the three other SPIONs). Also, the onset of aggregation upon lowering the pH occurs at a more acidic environment for the zwitterionic SPIONs. The zwitterionic, as well as neutral and anionic SPIONs, are stable for at least two hours above pH 5 with a constant hydrodynamic diameter from pH 5 to pH 13. It is well-established that the interactions between catechol and iron ions are influenced by pH [32 – 34]. At low pH, the protonation of the catechol OH groups hampers their binding to the SPION surface [35]. No experiment was performed at pH > 13, as iron hydroxide precipitates under these strongly basic conditions due to ligand exchange with hydroxide ions.

Next, the stabilities of the SPIONs to different salts were studied, including NaCl (containing only monovalent ions), MgCl₂ (featuring a divalent cation), and Na₂SO₄ (containing a divalent anion). As shown in Figure 3B, zwitterionic SPIONs are stable to NaCl concentrations as high as 1.0 M. We attribute the slight size increase at high concentration of NaCl to ions doping to the SPION surface through the association between the counterions in the solution [36]. In contrast, the neutral and anionic SPIONs are not able to withstand the high concentration (1 M) of NaCl. The stabilities of SPIONs in salt solutions containing divalent ions are shown in Figure 3, C and D. The SPIONs are relatively stable up to 100 mM Na₂SO₄, while a high concentration (1 M) of this salt induces aggregation of all SPIONs. MgCl₂ causes aggregation already at lower concentrations (10 mM). Only the zwitterionic SPIONs remain stable in the presence of 10 mM MgCl₂. Mg²⁺ most likely competes with the SPION surface for the ligands by forming magnesium catechol adducts [37]. Note that the cationic SPIONs were already aggregated prior to these experiments. These aggregates did not change in size very much subsequently.

We compared the DLS data of the four SPIONs after 2 h with the corresponding data obtained after 1, 30, and 70 days at different pH values and salt concentrations (Figures 4 and 5). Zwitterionic NPs are stable at pH 7 - 13 during the entire period. At pH 1 – 5, they had formed precipitates after 70 days. Interestingly, their size became smaller after 30 days at pH 5 which may be due to ligand exchange with citric acid present in the buffer. Neutral SPIONs slightly aggregated at pH 5 - 9 over time, while anionic SPIONs showed only short-term stability. Anionic SPIONs are stable only at pH 13, presumably as a result of a greater degree of charge repulsion between these

SPIONs at elevated pH. Cationic SPIONs aggregated during all tests.

In the presence of different salts, zwitterionic SPIONs remain well dispersed even after 70 days, as shown in Figure 5, A. In contrast, neutral and anionic SPIONs had aggregated after 70 days as shown in Figure 5, B and C. Thus, zwitterionic SPIONs display promising long-term stability compared to the neutral, anionic, and cationic counterparts, which makes them good candidates for further application.

Aldehyde Functionalization and Hydrazone Conjugation

Given that the zwitterionic ligand yields remarkably stable SPIONs, and given that zwitterionic ligands are also reported to minimize nonspecific absorption of the SPIONs, [13] we decided to develop these materials as a platform for further conjugation. We grafted benzaldehyde groups to the surface of the zwitterionic SPIONs, since aromatic aldehydes can react with many nitrogen nucleophiles under mild aqueous conditions to yield imines, hydrazones and oximes. As the benzaldehyde group is quite hydrophobic,
obtaining well-dispersed nanoparticles with a high surface coverage of benzaldehydes in aqueous solution puts stringent demands on the design of the ligand [38]. We decided to incorporate the zwitterionic choline phosphate moiety in the ligand [39]. Ligand 14 (Figure 6, A) was prepared in four steps, including a phosphorylation and a ring-opening reaction as well as amidation. The overall yield was low partly due to the challenges posed by the EDC-mediated amidation step, which had to be conducted in water-containing solvents to dissolve 13 and to prevent this compound from forming imines. EDC is easily hydrolyzed by water, requiring the use of an excess of EDC, causing its conjugation with one of the hydroxy groups of catechol (Scheme S1). It was possible to convert this side-product into the desired ligand 14 through the two-step procedure shown in Scheme S1. It was possible to control the aldehyde surface density of the SPIONs by working with different ratios of zwitterionic ligand 6 and zwitterionic aldehyde 14. We prepared four sets of SPIONs with

Figure 4. Mean hydrodynamic size (number fraction) of zwitterionic (A), neutral (B), anionic (C), and cationic (D) SPIONs at different pH as a function of time. Hydrodynamic sizes were measured by DLS at 25 °C 2 hours after sample preparation (black); after 1 day (red); 30 days (blue), and 70 days (cyan). The average size of aggregated samples is only an indicative number that reflects the degree of aggregation.
25%, 50%, 75%, and 100% of the aldehyde ligand. The hydrodynamic size was measured by DLS (Figure S5), showing that all of these SPIONs were well-dispersed in aqueous solution. This conclusion was confirmed by TEM analysis of the SPION sample prepared from a 1:1 mixture of 6 and 14 (Figure S6). All four SPIONs are stable up to 70 days. We also noticed that only a few aggregates formed in the sample of SPIONs coated with 100% 14 after four months’ storage. Together with the zwitterionic SPIONs made from 6 only, these samples were characterized by UV, which indicated the presence of the aromatic aldehyde group in 14, which has a maximum absorption at 270 nm. As shown in Figure 7, A, the peak at 270 nm increases with increasing fraction of the benzaldehyde ligand. To show that these aldehyde-functionalized SPIONs can be readily functionalized further, we reacted them with the fluorescent hydrazide dye NBD-CO-Hz in the presence of aniline as a catalyst (Figure 6, B). After purification by centrifugal filtration, the resulting zwitterionic SPIONs were characterized by UV (Figure 7, B) and fluorescence (Figure S7) spectroscopy. The normalized UV spectrum shows a peak around 470 nm which increases as the 14:6 ratio increases, which indicates that more NBD molecules become attached to the surface of the SPIONs which have a higher aldehyde coverage. The maximum absorption of NBD shifts from
425 nm in solution to 470 nm on the surface of the nanoparticles, which implies that NBD molecules experience a different environment on the nanoparticles. Also, by fluorescence we found an increased signal intensity of NBD as the aldehyde surface density is increased (Figure S7; NBD emits at 540 nm).

**Conclusions**

While aiming to develop systems-chemistry applications of SPIONs, we were unable to find protocols in the literature that enabled us to access stable dispersions of SPIONs in water that were amenable to dynamic covalent surface functionalization. This led us to investigate the stability of water-dispersed SPIONs coated by differently charged ligands (neutral, anionic,
cationic and zwitterionic) across a range of pHs and ionic strengths. The results show that the zwitterionic ligands are most efficient at stabilizing the aqueous solutions of SPIONs, which remain well-dispersed for the entire 2-month period during which we monitored the samples. Furthermore, a zwitterionic ligand carrying an aldehyde group has been synthesized that allows, for the first time, for facile further dynamic covalent SPION surface modification and potentially also bioconjugation. The aldehyde can be grafted on the surface of the SPIONs at an arbitrary percentage of coverage and readily reacts with a hydrazide under mild condition. These results suggest that this SPION platform holds considerable promise for biological and biomedical studies and surface supported dynamic combinatorial chemistry for applications in systems chemistry [40].
